

ABSTRACT OF THE DISCLOSURE

In a variable-gain digital filter of the prior art in which X is the number of bits of data after baseband processing and Y is the number of gain bits, the number of bits of input is $X + Y$ and the number of flip-flops required is equivalent for $(X + Y) \times n$ bits, thereby raising the problem of excessive circuit scale. In the variable-gain digital filter of the present invention, a selector and multiplier for regulating gain are arranged inside the digital filter whereby the number of bits of filter input is X , the number of flip-flops inside the filter is $X \times n$ bits, and a $(Y \times n \text{ bit})$ reduction in the number of flip-flops is enabled. The gain regulation circuit that was arranged to precede the prior-art filter is thus incorporated within the digital filter to enable a reduction in circuit scale.
